Economy Works Differently: Any Good Entrepreneur Drives Investment by Its Future Earnings Rather Than Its Spending, So Why Do Governments Drive by GDP (Consumption+ Investment Spending)?

Didier Vanoverberghe Mines ParisTech, PSL

GDP, even net of obsolescence (NDP) has to be considered only as an expense (investment is an expense; consumption is an expense). As an entrepreneur you will never manage your investments by looking only the expenses; it is clear you will make decisions on gains. As a person, will you look at the expenses you make to acquire stocks or at the gains? Thus it must have been clear that you will never manage a country by costs, so why do governments use GDP (consumption plus investment spending) to drive their economy? Governments should manage gains: wealth created, which is the full result you get from all these expenses.

Keywords: wealth, debt, macroeconomics, finance, unified theory, Friedman, Keynes, Barro Ricardo equivalence, 2 Cambridges controversy, capital, investment, valorisator, GDP, NDP, Permanent Income Hypothesis

INTRODUCTION

GDP, even net of obsolescence (NDP) has to be considered only as an expense (investment is an expense; consumption, export minus import, and change of stock, all these indicators are expenses). As an entrepreneur you will never manage your investments by looking only at the expenses; it is clear you will decide on gains. As a person, will you look at the expenses you make to acquire stocks or at the gains? Thus it must have been clear that you will never manage a country by costs, so why do governments use GDP (consumption plus investment spending) to drive their economy? Governments should manage gains: wealth created, which is the full result you get from all these expenses. The net gain from today's investment is the opportunity to invest, resulting from all future revenues received (salaries, taxes and free cash flow) minus this today's investment.

Drive by GDP is due to the classical way of macroeconomics. By managing one year (even several, but not all the future years), macroeconomics has made the same mistake since about 100 years, when Simon Kuznets and John Maynard Keynes made the GDP the key indicator of any economy.

We will show that each year, consumption plus the discounting sum of all revenues consumed resulting from the investment is no more than the wealth created, which is very different from the GDP.

In chapter1, we will explain the wealth creation mechanism using simplified figures for USA. In chapter 2 we give the wealth creation formulas per year: wealth created annually is very different from GDP (and NDP). In chapter 3, we conclude that the government will drive their country by using the level of Wealth of the Nation and the wealth created annually. In chapter 4 we provide real figures for 7

countries over 20 years and we applied a Leland approach to compute the optimum increase of Debt compared to the government wealth every year.

THE WEALTH CREATION MECHANISM

In this paper, we will generally use first capital letters for Stock and a first lowercase letter for a flow. (Wealth and Capital are Stocks; annual wealth created is a flow). We will use a prime mark when we use gross values (before obsolescence effects). In addition, in order to facilitate the understanding of the mechanisms of wealth creation, we will use approximate figures in the body of this text; the exact figures are presented in the appendix.

Like Keynes, we can say that production has two components: non-durable goods (c: consumption) and durable equipment (i': new machines called gross investment). In a closed economy, all that is produced is sold, thus equaling revenue (y'). Our example is presented in a closed economy, but the formulas are exact because we use revenue instead of GDP.

This equation is generally written as Keynes did it: y' = c+i'. In this formula, we can't say that the revenue y' is the result of the investment i'. All that is produced results from all the producing machines, the whole Capital. We can write it: y'=c+i'=a'*Capital, where -a'- is the (gross) revenue global factor. Thus y', c and i' are the consequences of the machines that produced them: the Capital.

For example, for the US, figures are about:

y' =\$ 20 trillion c =\$ 15 trillion

i'= \$ 5 trillion

Capital= \$ 100 trillion

The revenue productivity factor - a'-is around 20 % for the USA.

If, like Friedman, you wanted to look at the long term, then you would probably think like him, that your level of Wealth corresponds to all your future incomes. One dollar of income expected in the future is the result of an activity subject to the vagaries of the market. This hoped-for, and therefore unsecured, dollar is worth less than a stumbling dollar, secure, in your pocket today; the difference between the two is called the discount rate (we note it wac). With a discount rate of 6 % for US, we obtain that one dollar of expected income in one year, therefore not certain, is exchanged for 0.94 dollar sure today; thus you have to divide any one-year future flow by 1.06 (1.06 * 1.06 for 2 years etc.), that is the definition of a discount rate of 6 %. How to determine this rate? It will be by analyzing the placements. It turns out that this rate must be equal to the expected rate of the placement concerned. Indeed, if you buy a one dollar share today and the market expects 1.06 dollar in a year, for consistency if you immediately sell your rights at one year, i.e. 1.06 dollar expected in a year, then you will sell them today for 1 dollar. So 1.06 dollar unsecure in a year is exchanged 1 dollar today. The discount rate is, therefore, also 6 % for the activity concerned, like the 6 % of its expected return. By studying all USA activities, we find today this average rate of expected return.

Friedman suggests defining Wealth by the discounted sum of all future income. And there he made a mistake: you have to withdraw each year the reinvestments made (change in Capital), because by acquiring them, you will recover other future incomes (for example for an investor his wealth is not the discounting sum of his future profits but of his future free cash-flow). Wealth can be seen as your expected living standard for the future.

If we include the Debt effects and their interests, we will find that net Wealth is the discounted sum of all your future consumptions (this explains the framework of the Lucas 'utility function).

Let's investigate how wealth creation works. If you have 300 dollars invested at 6 %, and you consume 18 dollars every year then your "income will be permanent", constant, of 18 dollars per year, because the Wealth will remain unchanged of 300 dollars every year. For doing this, you need at the same time that your Capital which produces annual created wealth, income, and consumption, remains unchanged and therefore, in the case of the US that, you invest 6 % of this Capital, as much as the obsolescence of 6 %. This amounts to replacing the power of machines those ages or disappear, with the

equivalent in new machines (6%). With this investment, you can therefore exchange your 300 dollars of Wealth for 18 dollars of permanent annuity. In other words, the exchange Value of 18 dollars permanent annually and insecure, at the discount rate of 6%, is 300 dollars (18/6% = 300). Certainly, at this given moment, there is indeed a "mathematical equivalence" of this wealth created expected with this constant permanent income. In fact, in time, things will happen in a very different way, because you want to invest more than the obsolescence in order to grow.

If you consume only 5% of the Wealth and thus reinvest 1% more, you renounce to today consumption, in order to get growth next year. Your part of current wealth distributed is this time really equal economically to the "returns or pay-back" you will have, i.e. 15 dollars the first year (18-3), which are now growing at the rate of + 1% per year; thus Wealth (300 dollars) and wealth created (18 dollars) will grow each year by 1% and really reflect the evolution of the economy, not the static one-year view, called "permanent income" by Friedman, which would cause you to consume all annual created wealth. The first mathematical equality gives you the rate of return of 6%, that is to say a created wealth of 18 dollars (the flow) that is not different in the 2 cases. If you consume 5% of your Wealth (the Stock), i.e., 15 dollars, your Wealth will increase by the remaining 3 dollars and ultimately drop from 300 dollars to 303 dollars, etc. per year, leading to a growth of 1%. Your income will grow by 1%; fortunately, growth exists. That is the way growth works.

Suppose that, like the USA, you invest 5% of the capital every year, with an obsolescence of 4 %, thus all things being proportional at equilibrium, your Capital will increase in one year by 1%.

Note: Here the Capital considered is what we call the economic Capital. The economic Capital as a proxy for the Capital in historical cost; the only difference could be due to an imperfect estimation of obsolescence (depreciation and amortization). Obsolescence is the investment amount you need to make the Enterprise Value constant, thus the economic Capital. See Economy works differently in episode 3 (SSRN), to get a solution to the 2 Cambridge controversy.

HOW DOES WEALTH CREATION WORK?

We can therefore estimate how rich USA is. Its consumption being of 15,000 billion dollars, it is also, given our presentation, equal to 6% minus 1%, that is to say, 5% of the Wealth of the USA. Wealth is, therefore \$ 300 trillion (we can check that 300x 5% = 15 that is consumption).

This is equivalent to the Gordon-Shapiro formula by extending fcf to all revenues consumed (salaries, taxes, fcf).

The discounted sum of all income minus reinvestments is, therefore, \$ 300 trillion. This therefore represents the discounted sum of all future income minus the reinvestments that will make them grow, or again closed from the discounted sum of all your future consumption. It may sound like a lot, but at the end it is only "the equivalent" of 20 years of consumption.

If we now analyze the annual production, this consumption of \$ 15 trillion also represents 15% of the 100 trillion dollars of Capital. Consumption, therefore, allows the link between Wealth and Capital: c=15% *Capital= 5% Wealth. Here Capital is economic Capital, and its proxy is the Capital in historical cost (the only difference can come from a bad estimation of obsolescence).

By discounting the sum with an expected growth rate g, we get a kind of extended Gordon Shapiro formula, and extended Q of Tobin formula:

Wealth = $((a-g)/(discount_rate-g))$ * Capital, where a and g (Precisely g is the net rate of change of the Capital (after taking into account the obsolescence) are net ratios.

Thus, USA Wealth is today worth about 3 times the Capital (15% / 5%). Let us call this ratio of 3 between Wealth and Capital, the Valorisator, thus for any country at any time: Wealth= Valorisator * Capital (all these indicators depend on time, on Nations and activities, evolve, keeping this relation: the Valorisator was closed from 6 for the USA 20 years ago). The Valorisator is a kind of generalization of Tobin's Q for all revenues.

It demonstrates a cause-consequence ratio between all current Capital and all future incomes minus future reinvestments from these incomes. This should not surprise anyone. Income is split down into

salaries (labor) and capital income (dividends and interest on debt for financial investments, rents less charges for real estate). The valuation of companies already gives us the ratio between the discounted sum of dividends and interest on debt, which is called Enterprise Value, and Capital, which is of the order of 1; indeed, any investor who invests one dollar of Capital in a company must see the value of the company at least equal to 1. Knowing that consumption is 3 times the distributed Capital income, both will grow at the same rate; ratio 3 is established for their discounted sums (between consumption of capital income and consumption of labor income) and, therefore between Wealth and Capital. This ratio has nothing to do with the Keynes multiplier which is around 4 for the USA (income on investment) and would have covered one year return which was not possible, where the Valorisator is 3 and relates to the whole future (by discounting the future we get an immediate equivalent exchange Value).

As a consequence of the ratio between Wealth and Capital, at equilibrium, the change in Wealth will also be proportional to the change in Capital, called investment, in the same ratio of 3 for USA and France. The investment has a central effect, contrary to what Friedman asserted, and not on the variation in income for the year as seen from Keynes (multiplier), but on the set of variations of all future incomes minus the associated variations of reinvestments.

From the formula:

$$Wealth = ((a - g)/(discount_rate - g)) * Capital$$
⁽¹⁾

where a is the net revenue factor and g the net_investment, we get at equilibrium: (discount_rate-g)*Wealth = (a-g) *Capital.

Thus for the net wealth created we get:

wealth_created= discount_rate*Wealth =net_revenue - g *Capital+g*Wealth

wealth_created = net_revenue+ (Valorisator-1) g*Capital

wealth_created = net_revenue+ (Valorisator-1) *net_investment

wealth created= y'+ (Valorisator-1)*investment'-Valorisator * obsolescence

(= consumption+ Valorisator* investment'-Valorisator* Capital obsolescence)

Note: At equilibrium, it is possible to give a direct demonstration. Because Wealth is the discounted sum of all revenues minus reinvestment, the wealth created is the consumption and the Stocked parts. The Stocked part is the increase of Wealth. As a consequence of the Wealth definition, the increase of Wealth is the discounted sum of the increase in revenue minus increase in reinvestment.

In trillion (T) for USA, we get the difference between net wealth created and net domestic production: wealth_created=20+2*5-3 *4=\$ 18 T (you can check, it is also 6%*300).

You can't do a lot against obsolescence.

This net wealth created must be compare to net domestic production = 20 - 4 = 16 T

For the gross indicators the difference is very higher:

gdp= gross_revenue=y'= \$20 T must be compare to right criteria of decision

gross wealth_created = y'+(Valorisator-1) * investment' = 20+2*5 = 30 = 15+15, where investment effects equals the consumption effects, that is totally different from GDP

At equilibrium, one trillion more invested must be counted for 3 for making a decision not for1 as in GDP.

The Valorisator allows us to invest for a Nation, including the debt effects (by the change of wac).

The wealth created includes future salaries, profits and taxes; as we will see the Valorisator is different for each country and is closed today from 3 for USA (1 for the investors in a perfect market plus 2 for salaries and taxes).

If there is a change of equilibrium we will simply add the change of equilibrium effect:

delta(Valorisator)/Valorisator * Wealth0

In a real world, there is no guarantee of equilibrium, and of course it is positive to invest only if your investments create sufficient income, if they do not create anything or less than their amount, wealth

created is net losses. In addition, for the investors the Valorisator is reduce to the microeconomic Q of Tobin: (roc-g)/(wac-g); the first condition to invest (for investors) remains roc greater than wac. So the question is how to maximize Wealth under the investor condition of profitability.

If the government needs to borrow to invest, the wac will increase, depending of the amount.

CONCLUSION: WHAT DOES A GOVERNMENT HAVE TO DRIVE ANNUALLY?

Let's look at how the flow of wealth created over one year for the USA is used. With a rate of 6%, the wealth created is, therefore 6% * 300,000 = or 18,000 billion dollars. From these 18,000 billion dollars, 15,000billion dollars are consumed. In addition, USA invests 5,000 billion dollars in investments, creating 3 times more, ie, \$15,000 billion, while obsolescence eliminates 3 * 4,000, almost whatever we do. In summary, the annual added wealth is used as follows: 18,000 = 15,000 + 3*5,000 - 3*4,000.

After consumption, Wealth will increase from 18,000-15,000 that leads to 3,000 billion which is indeed 1% growth (initial Wealth is \$300,000 billion), or 3 times the net investment which is \$1,000 billion (note: 5,000-4,000). We will therefore get in the future, every year, 1% more income and investment.

On average, the investments weigh \$15,000 billion of created wealth while the GDP only counts them for \$5,000 billion. The GDP measures the expenditure for the year, where you have to steer all future wealth creation. Our Governments are therefore in total error in piloting the GDP, even over 3 years. Gross production is 20,000 billion dollars (15,000 consumption + 5,000 investments) while the gross wealth created over one year is 30,000 billion dollars: 15,000 consumption + 15,000 investment valorization. ("to valorizate" is to discount all future revenues minus future reinvestments (including 0 return investment variation, that is, increase in liquidity (+ decrease in liquidity), the two due to this investment, including the reinvestments)

To make a choice is to compare what you gain against what it costs. An investment will last and produce several years. The investment must therefore be compared to its discounted future revenues. Who will continue to drive spending where it is necessary to drive future revenues? Jobs, investments, debt, the economy works differently; it has to be managed differently. Here is the tool to manage what some call the Capital of stakeholders; without this new framework impossible to put the economy at the service of all (with that new approach, we can even start to promote ecology, sustainability, work at home ...). It should be obvious that in order to manage the economy of a country, we have to discount income from labor as income from Capital; in the past, economics has taken a wrong turn, let's start over again, remembering that money can be a good servant, but not our master.

The maximum Debt level would deserve an episode on its own. At this point, let's just say that no bank would consider only a year's income in determining your possible loan amount to buy a house, for example. The bank must consider all future changes in your income and, therefore, your Wealth. To determine a borrowing level, does a permanent contract with constant income worth the same as a fixedterm contract and the same as a permanent contract whose salary increases by 1%? Likewise, for a State, the answer is clear, Debt to GDP is, therefore, a ratio besides the subject; what counts is the Debt to Wealth ratio. If your income is 40,000 dollars and your debt-to-income ratio for the year exceeds 100% to buy your house and even if your loan is 150,000 dollars, is that a problem? You have 25 years to pay it off. If the Debt to Income (gdp) ratio exceeds 100% is it a problem? Debt divided by 25 years of income is only 4%. Even if we only take State revenues, it will be 8%. With a Wealth approach, traditional finance methods make it possible to answer the Debt amount question. Thus for the USA with 300,000 billion dollars in Wealth, or nearly 100,000 for the Government, \$25 trillion in Debt, it is significant but not insurmountable. Thus with a model of the Leland type, based on country competitiveness, we find that if we invest correctly, we can increase the Debt immediately by another 800 billion of optimized investment. This is quite logical, a good investment is creating in average three times its value at the beginning (the ratio decreases with the amount); during this time by increasing the Debt, the risk of not being able to repay the interest surely increases (costs of bankruptcy increases exponentially). This results in an increasing discount rate and as a consequence the decreasing of the Wealth. Expected gains and losses intersect at the maximum borrowed investment rate related to what that investment will produce. We must analyze neither averages nor marginal rates (even corrected for adjustment costs) but differential variations.

Another simple reason could be made. If the USA wac is 6% and a Bank would like a 2% wac, the maximum Debt should be a third of the Government Wealth, that is about \$33,000 billion. (For example, a constant annual revenue of 60\$ discounted at 6% worth 60/6% = 1000\$ exactly as a constant revenue of a third of 60 \$ that is 20\$ discounted at 2%: 20/2% = 1000\$).

These limits could be increased if you consider the dollars of Wealth outside of the USA. The Barro limit about the Barro-Ricardo equivalence (Debt has no effect on revenue over a long period) is that he never considers investments and their results (Valorisator * investment). His equations (it is very simple to check in "Are government Bonds net wealth", 1974) could be summarized by a Debt equation, where Debt is Bound (B) with a borrowing rate of r ; he finally writes: B(1+r) -rB - B=0 (even if he uses Overlapping Generations). By this way he does not take into account that if B is invested, B will create Valorisator* B = delta Wealth (from 3 to 6 times B if B is small) for the Nation (including taxes for Government). As B increases, its Valorisator decreases and bankruptcy costs increase by an increase of the discount rate, which decreases wealth creation. Thus there is an optimum Debt depending on the projects selected. Thus, Barro would have needed one generation step more to introduce the Valorisator effects on investments. The realistic figures are computed in the appendix depending on the activities selected (scenarios leads to Valorisator and change of Valorisator) demonstrating the utility to invest even by borrowing no more than the optimum.

Every morning when we wake up we can look at the planets, they are round, and they turn, so let's no longer listen to those who tell us that the earth is flat, and let's reason.

REAL COMPUTED FIGURES

To compute all figures, we use for each country all accounts of Eurostat Data (and OCDE when needed) plus financial results of the non-financial enterprise and their Debt and Stock (example SP500 for USA), plus banks publications (China, Russia). We use capillarity to compute all the figures: first we use stock results and financial results of main companies; we generalize results to the non-financial enterprise sector, including revenues and taxes. Secondly, we compute discounted sums using all accounts for the financial sector. Thirdly we compute the government and institutions sector. At least we compute the Household sector. All flows of all accounts are discounted. (Note we compute the Rest of the world by assuming the wac is similar to the country).
